The strategies, methods and indicators presented here are given for educational purposes only and should not be construed as investment advice. Be aware that the profitable performance presented here is based upon hypothetical trading with the benefit of hindsight and can in no way be assumed nor can it be claimed that the strategy and methods presented here will be profitable in the future or that they will not result in losses

In previous working papers we examined a trading system that used the velocity of prices fit by a least squares straight line through “N” past prices, to determine buy and sell points. The reasoning behind this type of system was to only trade when the straight-line slope or velocity was above a certain threshold. Many times, during the day prices meandering around without a notable trend. At these times we do not wish to trade because of the whipsaws losses that occur from this type of price action. When a price trend finally starts, the velocity of that price trend moves above some minimum threshold value. Thus, the velocity system would only issue a trade when certain velocity barriers were crossed.

The Least Squares polynomial is determined by minimizing the sum of the squares of the difference between the N prices and the value of the polynomial line.

$$\text{err}^2(t) = [\text{Price}(t) - (a + b*t)]^2 \text{ = error squared}$$

$t=N$

$$\text{Minimize}(a,b) \sum_{t=1}^N \text{err}^2(t)$$

This mathematical technique has an exact solution and dates back to Gauss in the 1800's.

Recently much work has been done in what is called robust regression and outlier detection techniques, Ref [1]. Robust regression techniques are now defined by a measure called the “breakdown point”. The breakdown point is loosely defined as the smallest amount of bad data points that can cause the regression coefficient solutions to take on values some distance from their true values. Unfortunately, the Least Squares technique has a breakdown point of $1/N$. In other words, only one bad data point can significantly change the computation of the velocity or slope of a straight line. The median of a set of numbers has a breakdown point of 50%. This is because when 50% of the numbers are bad then there is no way of telling which are bad numbers and which are the good numbers. 50% is the highest breakdown point.

The least absolute deviation (LAD) regression estimator from Ref [1] is

$i=N$

$$\text{Minimize}(a,b) \sum_{i=1}^N |\text{err}(i)|$$

and has a breakdown point of 29.8% . For the LAD this means around $\frac{1}{4}$ of the price points can be bad before the computations of a and b become erroneous. Siegel Ref [2], in his paper

“Robust regression using repeated medians”, introduced a technique for finding the slope that has a 50% breakpoint. The repeated median is also described in Ref [1].

While the repeated median technique may sound complicated it is quite easy to compute. Here's how. For demonstration purposes let's suppose we have 15 data points on an x, y graph such that,

X	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
Y	1	2	10	4	5	6	7	8	9	18	11	12	13	18	15	20

We've added two bad Y points at X positions 3,10, 14 and 16. To calculate the repeated median slope we would take the slope of every pair of y values and then find the median of all the pairs of slopes. For this example, we would take

slope	1	$y(2)-y(1)/(2-1) =$	1.00
slope	2	$y(3)-y(1)/(3-1)=$	4.50
slope	3	$y(4)-y(1)/4-1)=$	1.00
slope	4	$y(5)-y(1)/(5-1)=$	1.00
slope	5	$y(6)-y(1)/(6-1)=$	1.00
slope	6	$y(7)-y(1)/(7-1)=$	1.00
slope	7	$y(8)-y(1)/(8-1)=$	1.00
slope	8	$y(9)-y(1)/(9-1)=$	1.00
slope	9	$y(10)-y(1)/(10-1)=$	1.89
slope	10	$y(11)-y(1)/(11-1)=$	1.00
slope	11	$y(12)-y(1)/(12-1)=$	1.00
slope	12	$y(13)-y(1)/(13-1)=$	1.00
slope	13	$y(14)-y(1)/(14-1)=$	1.31
slope	14	$y(15)-y(1)/(15-1)=$	1.00
slope	14	$y(16)-y(1)/(16-1)=$	1.27
		Median =	1.00

The median slope of the above is 1. The above process is repeated for:

$(y(2)-y(i))/(2-i)$, $i=1$ to 15 $i \neq 2$,

$(y(3)-y(i))/(3-i)$, $i=1$ to 15 $i \neq 3$,

.....

$(y(16)-y(i))/(16-i)$, $i=1$ to 16 $i \neq 16$.

The final slope is then the **median of all the medians calculated above**. While the repeated median looks redundant because the very first calculation produced the correct slope, price data is not so nicely distributed as our example and the extra calculations are needed to assure that the outliers are eliminated.

The mathematical formula for the above is

$$\text{Slope}(t) = \text{median}_i \{ \text{median}_{j \neq i} [\text{price}(t) - \text{price}(t-j)] / (i-j) \}$$

Figure 1 below shows a plot of the x,y numbers above with the repeated median line and the least squares line on the graph. Notice how the bad points draw the least squares line towards them while the repeated median line is completely unaffected by the outliers. The least Squares line is given by the formula $y = -0.65 + 1.1074x$. The true line is given by the formula $y = x$. From this simple example we can observe how noise has distorted the least squares estimates of **a** and **b**, where $y = a + bx$.

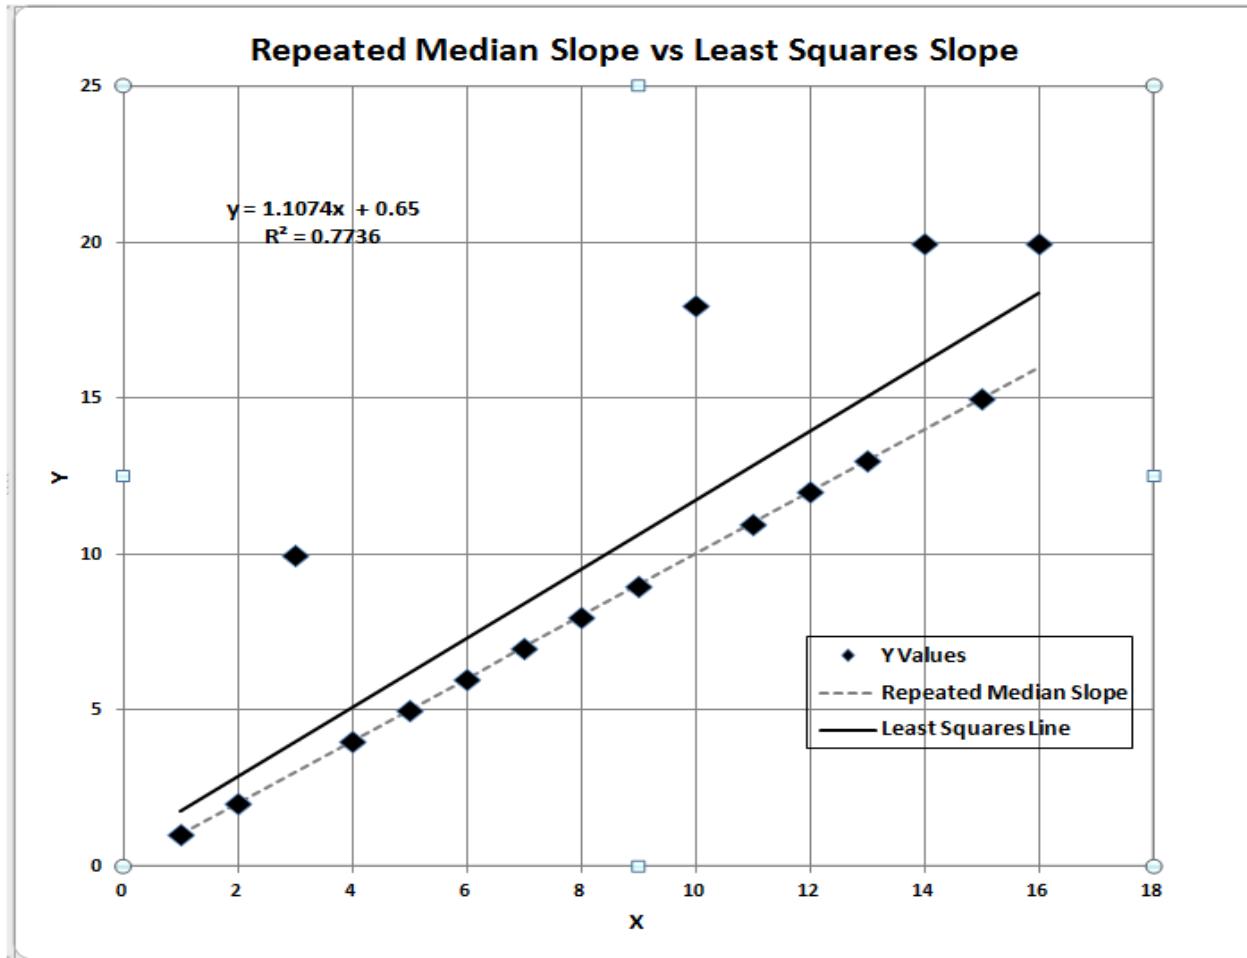

Figure 1 Repeated Median Slope vs Least Squares Slope.

The Repeated Median Velocity (RMedV) System Defined

Here we will use the repeated median slope to create a trading system. For a straight line the velocity is equal to the slope. The repeated median velocity, also called the **robust velocity**, has the advantage that it is a natural random price noise inhibitor. We can create a system such that unless the repeated median velocity using N past price bars is greater than some threshold value we will not buy or sell. A large percentage of price movements are just noise which generates a lot of back and forth movements of small magnitudes. This back and forth movement creates many false buy and sell signals. However, using the repeated median velocity over N past prices, we will attempt to filter out many of the small price noise movements by requiring that the repeated median velocity to be greater than some threshold before we act.

At each price bar we calculate the repeated median velocity (**RMedV**) from the formula above. When the velocity is greater than the threshold amount *vup* we will go long. When the velocity is less than the threshold amount *-vdn* we will go short.

The Repeated Median Velocity Trading Strategy

Buy Rule:

IF **RMedV** is greater than the threshold amount *vup* then buy at the market.

Sell Rule:

IF **RMedV** is less than the threshold amount *-vdn* then sell at the market.

Friday Exit Rule:

Discussion of Euro Futures Prices

The Euro (EC) is traded on Globex. On Globex the EC is traded on a 23hour basis . On Monday Through Thursday the EC closes at 1600hr CST and reopens at 1700hr CST. On Friday the EC closes at 1600hr CST and reopens on Sunday at 1700hr CST. For this paper we will trade all hours that Globex is open, but we will close all open positions on Friday at 1600hr CST and resume trading at 1700hr on Sunday. Please note that the strategy might not have a buy or sell signal when trading opens on Sunday. To test this strategy, we will use 5-minute bar prices of the EC futures contract for the 11+ years from January 2, 2008 to April 27, 2018. We will use the 52 weeks of EC 5 min bar prices following Friday 4/27/2018, from Sunday 4/29/2018 to Friday 4/26/2019, to see how the Repeated Median Velocity out-of-sample metric filter found on the 1/1/2008 to 4/27/2018 price data performed on *future* data it had not seen.

Data Discussion

To test this strategy, we will use 5-minute bar prices of the Euro traded on Globex known by the symbol EC for the 586 weeks from January 2, 2008 to April 26,2019.

We will test this strategy with the above EC 5min bars on a walk forward basis, as will be described below. In TradeStation (TS) or MultiCharts(MC), we will run the RMedV Strategy on the EC 5 min bar data from January 3, 2008 to December 27, 2018. We will breakup and create 30-day calendar *in-sample* sections along with their corresponding one calendar week *out-of-sample* sections from the 586 weeks of EC (see Walk forward Testing below) creating 586 out-of-sample weeks. To create our walk forward files we will use the *add-in* software product called the Power Walk Forward Optimizer (PWFO) <http://meyersanalytics.com/Walk-Forward-Optimization.html> . In TS/MC, we will run the PWFO strategy *add-in* along with the RMedV Strategy on the EC 5min data from 1/3/2008 to 4/26/2019 The PWFO will breakup and create 30-day calendar in-sample sections along with their corresponding one calendar week out-of-sample sections from the 586 weeks of EC (see Walk Forward Testing below) creating 586 out-of-sample weeks. Note the first in-sample week will be from 1/3/2008 to 2/1/2008 and the first out-of-sample week will be from 02/03/2008 to 02/08/08.

Testing the Repeated Median Velocity System (RMedV**) Using Walk Forward Optimization**

There are three strategy inputs to determine:

1. *N*, the lookback period to calculate the **RMedV**.

2. *vup*, the threshold amount that RMedV must be greater than to issue a buy signal
3. *vdn*, the threshold amount that RMedV must be less than to issue a sell signal

We will test the RMedV strategy with the above EC 5 min bars on a ***walk forward basis***, as will be described below.

What Is A Walk Forward Optimization with In-Sample Section and Out-Of-Sample Sections?

Whenever we do a TradeStation(TS) or MultiCharts(MC) optimization on a number of different strategy inputs, TS/MC generates an *in-sample* report of performance metrics (total net profits, number of losing trades, etc.) vs these different strategy inputs. If the report is sorted on say the total net profits(*tnp*) performance metric column then the highest *tnp* would correspond to a certain set of inputs. This is called an *in-sample (IS) section*. If we choose a set of strategy inputs from this report based upon some performance metric, we have no idea whether these strategy inputs will produce the same results on future price data or data they have not been tested on. Price data that is not in the in-sample section is defined as *out-of-sample (OOS) data*. Since the performance metrics generated in the in-sample section are usually mostly due to "curve fitting" or "data mining" it is important to see how the strategy inputs chosen from the in-sample section perform on out-of-sample price data.

What do we mean by "*curve fitting*" or *data mining*? As a simple example, suppose you were taking a subway to work. In the subway car you are in, suppose you counted the number of blond women in that car and suppose the percent of blond women vs all other women hair colors was 80%. Being that you can't observe what is in the other subway cars, you would assume that all the other subway cars and perhaps all women in general had the same percentage of blond hair. This observation was due to chance. That is an example of curve fitting. The same goes for combinatorial searches. You are observing results from a finite sample of data without knowing the data outside the sample you examined.

Walk forward analysis attempts to minimize the curve fitting of price noise by using the law of averages from the Central Limit Theorem on the out-of-sample performance. In walk forward analysis the data is broken up into many in-sample and out-of-sample sections. Usually for any strategy, one has some performance metric selection procedure, which we will call a *filter*, used to select the input parameters from the in-sample optimization run. For instance, a *filter* example might be all cases that have a profit factor (PF) greater than 1 and less than 3. For the number of cases left, we might select the case that had the best percent profit. This procedure would leave you with one case in the in-sample section and its associated strategy input parameters. Now suppose we ran our optimization on each of our many in-sample sections and applied our filter to each in-sample section. We would then use the strategy input parameters found by the *filter* in each in-sample section on the out-of-sample section immediately following that in-sample section. The strategy input parameters found in each in-sample section and applied to each out-of-sample section would produce independent net profits or losses for each of the out-of-sample sections. Using this method, we now have "x" number of independent out-of-sample section profit and losses from our filter. If we take the average of these out-of-sample section net profits and losses, then we will have an estimate of how our strategy will perform on average. Due to the Central Limit Theorem, as the number of out-of-sample sections increases, the spurious noise results in the out-of-sample section performance tend to average out to zero in the limit, leaving us with what to expect from our strategy and filter. ***Mathematical note: This assumption***

assumes that the out-of-sample returns are from probability distributions that have a finite variance.

Why use the walk forward technique? Why not just perform an optimization on the whole price series and choose the input parameters that give the best total net profits or profit factor? Surely the price noise cancels itself out with such a large number of in-sample trades. Unfortunately, nothing could be farther from the truth! Optimization is a misnomer and should really be called combinatorial search. As stated above, whenever we run a combinatorial search over many different combinations of input parameters on noisy data on a fixed number of prices, **no matter how many**, the best performance parameters found are guaranteed to be due to “*curve fitting*” the noise and signal. The price series that we trade consists of random spurious price movements, which we call noise, and repeatable price patterns (*if they exist*). When we run, for example, 5000 different inputs parameter combinations, the best performance parameters will be from those strategy input variables that are able to produce profits from the price pattern **and** the random spurious movements. While the price patterns will repeat, the same spurious price movements will not. If the spurious price movements that were captured by a certain set of input parameters were a large part of the total net profits, as they are in real intraday price series, then choosing these input parameters will produce losses when traded on future data. These losses occur because the spurious price movements will not be repeated in the same way. This is why strategy optimization or combinatorial searches with no out-of-sample testing cause loses when traded in real time from something that looked great in the in-sample section.

In order to gain confidence that our input parameter selection method using the optimization output of the in-sample data will produce profits, we must test the input parameters we found in the in-sample section on out-of-sample data. In addition, we must perform the in-sample/out-of-sample analysis many times. Why not just do the out-of-sample analysis once or just 10 times? Well just as in Poker or any card game, where there is considerable variation in luck from hand to hand, walk forward out-of-sample analysis gives considerable variation in week-to-week out-of-sample profit “luck”. That is, by pure chance we may have chosen some input parameter set that did well in the in-sample section data **and** the out-of-sample section data. In order to minimize this type of “luck”, statistically, we must repeat the walk forward out-of-sample (oos) analysis over many (>50) in-sample/out-of-sample sections and take an average over all out-of-sample sections. This average gives us an expected out-of-sample return and a standard deviation of out-of-sample returns which allows us to statistically estimate the expected equity and its range for N out-of-sample periods in the future

Finding the Strategy Parameters Using Walk Forward Optimization

There are three strategy parameters to find N , v_{up} , v_{dn} .

For the test data we will run the Multicharts64 optimization engine on **EC 5** min price bars from 1/3/2008 to 4/26/2019 with the below optimization ranges for the RMedV strategy inputs. I will create a 30-calendar day in-sample periods each followed by a 7 day out-of-sample period (See Table 1 for the in-sample/out-of-sample periods). This will create 586 in-sample 30-day periods followed by 586 out-of-sample 7-day periods from 1/3/2008 to 4/26/2019.

We will use the following strategy input optimization ranges.

N from 6 to 30 in steps of 1

vup from 0.25 to 3.5 steps of 0.25

vdn from 0.25 to 3.5 in steps of 0.25

Fri Close we will close all open positions on Friday at 1600hr CST and resume trading at 1700hr on Sunday

Mult= $1788^*\sqrt{N}$. Note: this normalizes the RMedV Velocity range for each N to one standard deviation. Else the Velocity would have different ranges for different N, and it would be difficult to find a vup and vdn that worked for all N ranges. See Appendix 1 for a detailed explanation.

This will produce 4900 different input combinations or cases of the strategy input parameters. for each of the 586 in-sample/out-of-sample files for the approximately 11+ years of 5 min bar EC prices from 1/3/2008 to 4/26/2019.

The question we are attempting to answer statistically is which performance metric or combination of performance metrics (which we will call a **filter**) applied to the in-sample section will produce in-sample strategy inputs that produce statistically valid average profits in the out-of-sample section. In other words, we wish to find a performance metric **filter** that we can apply to the in-sample section that can give us strategy inputs that will produce, on average, good trading results in the future.

When TS/MC does an optimization over many combinations of inputs, it creates an output page that has as its rows each strategy input combination and as its columns various trading performance measures such as Profit Factor, Total Net Profits, etc. An example of a simple filter would be to choose the strategy input optimization row in the in-sample section that had the highest Net Profit or perhaps a row that had the best Profit Factor with their associated strategy inputs. Unfortunately, it was found that this type of simple metric performance filter very rarely produces good out-of-sample results. More complicated metric filters can produce good out-of-sample results minimizing spurious price movement biases in the in-sample selection of strategy inputs.

The combination metric filters are found by a program called WFME64v8x. Details of this program can be found at <http://meyersanalytics.com/wfme.html>.

All PWFO file metrics used by the WFME64v8x are described at <http://meyersanalytics.com/Walk-Forward-Optimization.html>.

We will use the WFME64 v8x program to find one in-sample combination-metric filter applied to each in-sample section which gives a set of strategy inputs which are then applied to each following out-of-sample section. This will consist 534 in-sample and out-of-sample sections. We will leave the 52 sections of EC data from 4/29/18 to 4/26/2019 out of the WFME64 calculations so that we can see how the metric filters found by the WFME64 performed on these 52 following *future* weeks which was not included in the original WFME64 run.

Here is the metric combination **filter** found by the WFME64 v8x program that was used in this paper. High profit factors (**pf**) in the in-sample section usually mean poor performance in the out-of-sample-section. This is a kind of reversion to the mean. So, in the in-sample (IS) section we eliminate all strategy input rows that have the in-sample metric **pf>2**. In addition, a high **Kendall rank correlation coefficient (ktau)** in the in-sample section also usually means poor

performance in the out-of-sample-section. This is also a kind of reversion to the mean. So, in the in-sample section we eliminate all strategy input rows that have the in-sample metric **ktau>50**. Using the **pf-ktau** elimination screen, as described, there can still be 100's of rows left in the in-sample section. The PWFO generates the performance metric named **eqTrn**. This metric is **Slope of the In-Sample Trade Equity Trend Line for a given set of strategy inputs.** Let us choose the 15 rows in the in-sample section that contain the **maximum eqTrn** values from the rows that are left from the **pf-ktau** screen. In other words, we sort **eqTrn** from high to low, eliminate the rows that have **pf>2, ktau>50** and then choose the largest 15 **eqTrn** rows of whatever is left. This filter will now leave 15 cases or rows in the in-sample section that satisfy the above filter conditions. We call this filter **t15eqTrn |p≤2ktau≤50** where **t15eqTrn** means the top or maximum **15 eqTrn** rows left *after* the **pf-ktau** in-sample row elimination. Suppose for this filter, within the 15 in-sample rows that are left, we want the row that has the highest value of the column metric called **mWb/mLb**. **mWb/mLb** is the Ratio of the Median of Winning Bars to the Median of Losing Bars for all trades in the in-sample section for a given set of strategy inputs. We abbreviate this final filter as **t15eqTrn |p≤2|ktau≤50- mWb|mLb**. For each in-sample section this filter leaves only one row in the in-sample section with its associated strategy inputs and following out-of-sample net profit in the out-of-sample section using the strategy inputs found in the in-sample section. This **t15eqTrn |p≤2|ktau≤50-mWb|mLb filter** is then applied to each of the 534 in-sample sections which give 534 sets of strategy inputs that are used to produce the corresponding 534 out-of-sample performance results. The average out-of-sample performance is calculated from these 534 out-of-sample performance results. In addition, many other important out-of-sample performance statistics for this filter are calculated and summarized.

Figure 2 shows such a computer run along with a small sample of other WFME64 filter combinations that are constructed in a similar manner. **Row 9** of the sample output in **Figure 2** shows the results of the filter discussed above.

Bootstrap Probability of Filter Results.

Using modern "Bootstrap" techniques, we can calculate the probability of obtaining our filter's total out-of-sample **net** profits by chance. Here's how the bootstrap technique is applied. Suppose as an example, we have 500 files of in-sample/out-of-sample data. A mirror random filter is created. Instead of picking an out-of-sample net profit (OSNP) from a **filter** row as before, the mirror filter picks a **random** row's OSNP in each of the 500 files. We repeat this random picking in each of the 500 files 5000 times. Each of the 5000 mirror filters will choose a random row's OSNP of their own in each of the 500 files. At the end, each of the 5000 mirror filters will have 500 **random** OSNP's picked from the rows of the 500 files. The sum of the 5000 random OSNP picks for each mirror filter will generate a random total out-of-sample net profit (**toNP**) or final random equity. The average and standard deviation of the 5000-mirror filter's different random **toNPs** will allow us to calculate the chance probability of our above chosen filter's **toNP**. Thus, given the mirror filter's bootstrap random **toNP** average and standard deviation, we can calculate the probability of obtaining our chosen filter's **toNP** by pure chance alone. **Figure 2** lists the 5000-mirror filter's bootstrap average for our 534 out-of-sample files of **(\$171)** with a bootstrap standard deviation of **\$87.8**. (Side Note. The average is the average per out-of-sample period(weekly). So, the average for the random selection would be the random (Average Random toNP/534) and the average net weekly for the filter from **Figure 2, Row 9** would be the **filter toNP/ (# of OOS)** periods traded or **175645/502=349.89**. The probability of obtaining our filters average weekly net profit of **349.89** is **1.47x10⁻⁹** which is **5.9** standard

deviations from the bootstrap average. For our filter, in Row 9, the expected number of cases that we could obtain by pure chance that would match or exceed **\$349.89**
is $[1-(1- 1.28 \times 10^{-9})^{172980}] \approx 172980 \times 1.47 \times 10^{-9} = 0.0025$ where **172980** is the total number of different filters we looked at in this run. This number is much less than one, so it is improbable that our result was due to pure chance

Results

Figure 1 presents a graph of the equity curve generated by using the WFME64 filter on the 534 weeks ending 2/8/2008 – 4/27/18 and the equity curve on the 52 weeks following until 4/26/2019(note the starting date 1/2/2008 was part of the first 30 day in-sample period). The equity curves are plotted from Equity and Net Equity columns in Table 1. Plotted on the equity curves is the 2nd Order Polynomial curve. The blue line is the equity curve without commissions and the red dots on the blue line are new highs in equity. The brown line is the equity curve with commissions and the green dots are the new highs in net equity. The grey line is the EC weekly closing prices superimposed on the Equity Chart. The vertical dotted red line on the right separates the future excluded period equity from 4/27/18 to 4/27/19. This is what would have happened if you used the strategy inputs found by the filter **t15eqTrn|p≤2|ktau≤50-mWb|mLb** on data not included in the initial run.

Figure 2 shows such a computer run along with a small sample of other WFME64 filter combinations that are constructed in a similar manner. **Row 9** of the sample output in **Figure 2** shows the results of the filter discussed above.

Figure 3 presents the out-of-sample EC 5-minute bar chart of all the buy and sell signals of the WFME64 filter 11/28/18 to 12/7/18 with the RMedV Indicator or those dates.

Table 1 below presents a table of the 534 plus the 52 future weeks in-sample and out-of-sample dates, the WFME **Filter** selected, strategy inputs and the weekly out-of-sample profit/loss results using the **t15eqTrn|p≤2|ktau≤50-mWb|mLb** filter described above.

Discussion of Strategy Performance of the WFME64 run

In **Figure 2, Row 9** is the filter chosen, **t15eqTrn|p≤2|ktau≤50-mWb|mLb**. This Metric Filter produced \$175,645 net profits after costs in 534 weeks and \$14005 net profits after costs in the withheld 52 weeks from the initial WFME run. The spreadsheet columns present some statistics that are of interest for the filter. An interesting statistic is **Blw**. **Blw** is the maximum number of weeks the **OOS** equity curve for this filter failed to make a new high. Blw is 53 weeks for this filter. This means that 53 weeks was the longest time that the equity for this strategy failed to make a new equity high in the 534 out-of-sample weeks. For this strategy, the **%P** (% of weekly oos periods that are positive) was **53%**, and the **%Wtr** (The % of all oos trades that are positive) was **45%**. This low **%Wtr** was made up for by **oW/oL** (average oos winning trades/average oos losing trades) equal to 1.67.

To see the effect of walk forward analysis, look at **Table 1**. Notice how the input parameters **N**, **vup**, **vdn** take sudden jumps from high to low and back. This is the walk forward process quickly adapting to changing volatility conditions in the in-sample sample. In addition, notice how often **N** changes from 6 to 30. When the data gets very noisy with a lot of spurious price

movements, the look back period, N, should be higher. During other times when the noise level is not as much N can be lower to get onboard a trend faster.

Figure 1 presents a graph of the equity curve using the **t15eqTrn|p≤2|ktau≤50-mWb|mLb filter** on the 534 weeks of out-of-sample data. Notice how the equity curve follows the 2nd order polynomial trend line with an R² of 0.96. This R² dropped to 0.95 for the net equity curve.

Using this filter, the strategy generated a profit of \$189,650 net equity after commissions and slippage of \$20/trade trading one EC contract for the total 586 weeks. From **Table 1**, the largest losing week was -\$7100 on the week ending 11/21/2008. The largest drawdown was -\$14590 from the week ending on 6/12/09 to 4/2/10. This drawdown lasted 42 weeks and took 6 weeks to recover and make a new equity. The second largest drawdown was -\$11620 from the week ending on 11/11/16 to 4/28/17. This drawdown lasted 24 weeks and took 27 weeks to recover and make a new equity. The *future* period that was not included in the WFME64 run from 4/29/18 to 4/26/19 was a volatile down market yet the RMedV strategy/WFME filter did well making a net profit of \$14005 during that one-year time frame.

Lastly, as can be seen in **Figure 2**, the top 15 filters all did very well in the 52 *future* weeks from 4/27/18 to 4/26/2019 following the original analysis.

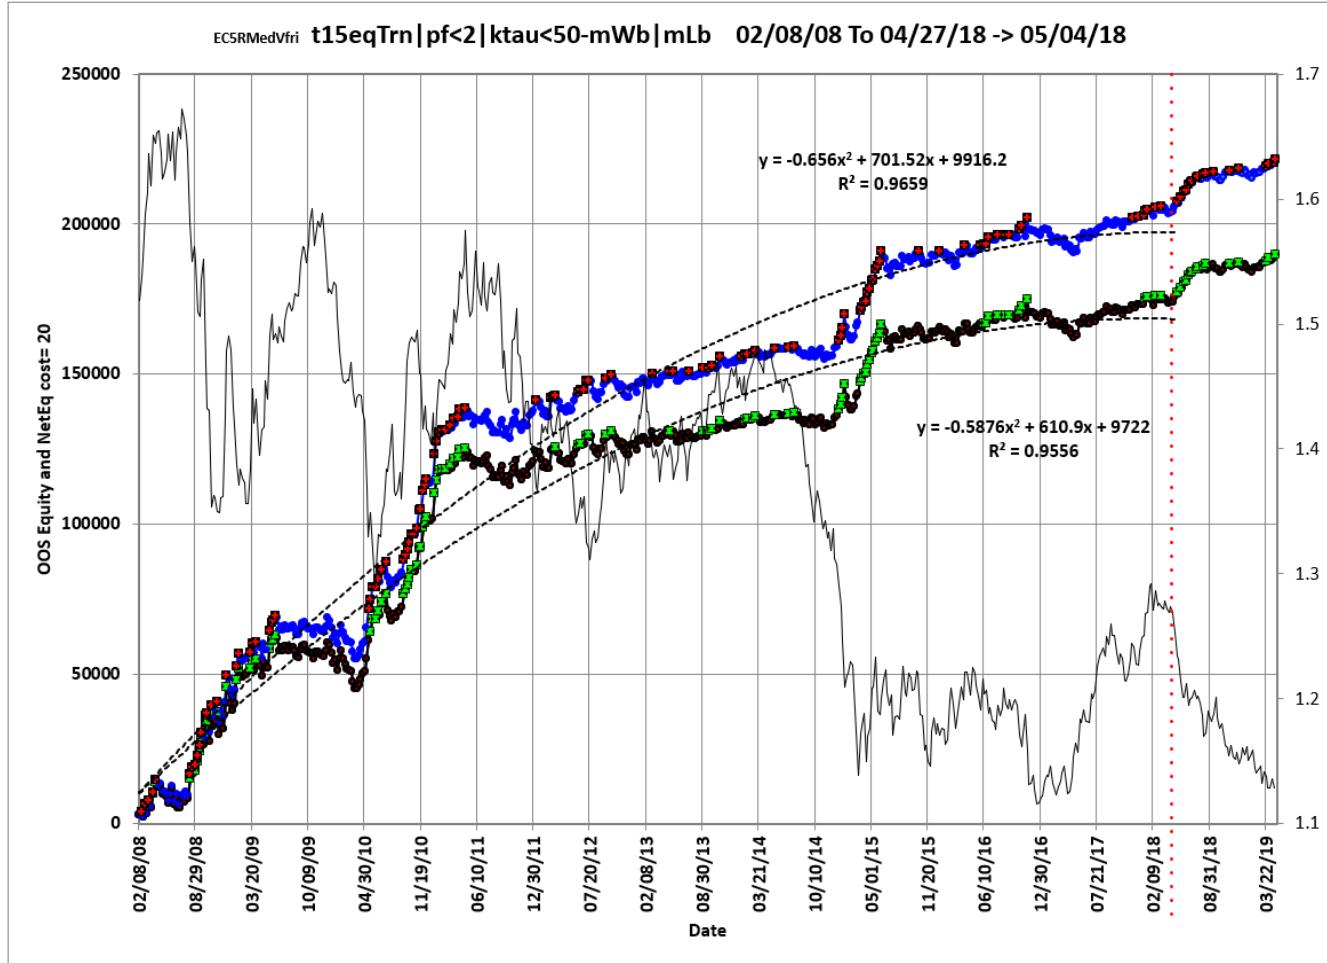

In observing Table 1 we can see that this strategy and filter made trades from a low of no trades in 32 of the 534 weeks to a high of 21 trades/week with an average of 3 trades/week in the weeks it did trade.

Figure 1 Graph of RMedV Strategy OOS Net Equity Applying the WFME64 Filter Each Week to In-Sample RMedV EC5min Bar Prices 2/08/2008 to 4/27/2018 >>4/26/2019

Note: The blue line is the equity curve without commissions and the red dots on the blue line are new highs in equity. The brown line is the equity curve with commissions of \$20/round trip trade and the green dots are the new highs in net equity. The grey line is the EC Weekly Closing prices superimposed on the Equity Chart. The vertical dotted red line on the right separates the future excluded period equity from 4/29/18 to 4/26/19. This is what would have happened if you used $t15eqTrn|pf<2|ktau<50-mWb|mLb$ filter on future data 4/29/2018-4/26/19 which was not included in the WFME filter run.

The WFME64 v8X AVE File Output Cols are defined as follows

❖ Row 1 Columns:

A=The PWFO Stub, **B**=File Start Date, **C**=File End Date, **D**= Number of oos periods (in this example weeks), **N**= Bootstrap average, **O**= Bootstrap Standard Deviation, **P**=Number of filters run, **U**= Cost and slippage per trade

❖ Row 1 and Row 2 Columns AA, AB, AC, AD, AE Future Results Not Included in the WFME64 Run. These set of results show how it would turn out if the Strategy Inputs/Filter was used on pwfo files not included in the WFME64 run.

Row 1 Col AB: Future PWFO File Start Date

Row 1 Col AC: Future PWFO File End Date

Row 1 Col AD: Future Number of PWFO Files not included in the WFME64 run (in this example weeks)

Row 1 Col AH: Number of Total oos+future PWFO Files

❖ Row 2 to Last Row Columns: A through AH

Col A: *The Strategy Input/Filter Names* Example Row 9: **t50mLTr|lr<3r2<80/nt>5-mDev**.

Col B: *toGP* - Total out-of-sample(oos) gross profit for these 347 oos periods (= weeks).

Col C: *toNP* - Total out-of-sample(oos) Net profit (toGP-Number of Trade Weeks*cost) for the 347 oos periods.

Col D: *aoGP* - Average oos gross profit for the 347 oos periods
Col E: *aoTr* - Average oos profit per trade
Col F: *ao#T* - Average number of oos trades per week
Col G: *std* - he standard deviation of the 347 oos period profits and losses
Col H: *skew* - The Skew statistic of the 347 oos period profits and losses
Col I: *kur* - he kurtosis statistic of the 347 oos period profits and losses
Col J: *t* - The student t statistic for the 347 oos periods. The higher the t statistic the higher the probability that this result was not due to pure chance
Col K: *oW/oL* - Ratio of average oos winning trades divided by average oos losing trades.
Col L: *%Wtr* - he percentage if oos winning trades
Col M: *%P* - percent of all oos periods that were profitable.
Col N: *LLtr* - The largest losing oos trade in all oos periods
Col O: *LLp* - The largest losing oos period
Col P: *eqDD* - The oos equity drawdown
Col Q: *wpr* - The largest number of winning oos periods (weeks) in a row.
Col R: *lpr* - he largest number of losing oos periods in a row
Col S: *#* - The number of oos periods this filter produced any profit or loss. Note for some oos periods there can be no strategy inputs that satisfy a given filters criteria and no trades will be made during that period.
Col T: *eqA2* - The acceleration of a 2nd order polynomial fit to the oos equity curve.
Col U: *Dev^2* - measure of equity curve smoothness. The square root of the average (equity curve minus a straight line)²
Col V: *KTau^2* - The Kendall rank coefficient is often used as a test statistic in a statistical hypothesis test to establish whether two variables may be regarded as statistically dependent. This test is non-parametric, as it does not rely on any assumptions on the distributions of X or Y or the distribution of (X,Y)
Col W: *eqR2* - The correlation coefficient(R^2) of a straight line fit to the equity curve.
Col X: *Blw* - The maximum number of oos periods the oos equity curve failed to make a new high.
Col Y: *BE* - Break even in oos periods. Assuming the average and standard deviation are from a normal distribution, this is the number of oos periods you would have to trade to have a 98% probability that your oos equity is above zero.
Col Z: *tkr/bl* = $t^*k\tau^*eqR2/Blw$ a measure of how good the filter fit is.
Col AB: *toGPx* Total gross profit for the 52 future excluded periods (for this run periods = weeks).
Col AC: *toNPx* Total Net profit (toGP-Number of Trade Weeks(#x)*cost) for the 52 future excluded periods.
Col AD: *aoTrx* Average profit per trade for the 52 future excluded periods
Col AE: *aoNTx* Average number of trades per week for the 52 future excluded periods
Col AF: *#x* The number of the 52 future excluded periods this strategy/filter traded. Note for some periods there can be no strategy inputs/filter that satisfy the Strategy Inputs/Filter criteria and no trades will be made during that period.
Col AG: *tOnpNet* - toNP+toNPx = Total Net Profits of oos+future periods
Col AH: *Prob* - The probability that the filters toNP was due to pure chance.

Figure 3 The out-of-sample 5-minute bar chart of all the RMedV Strategy buy and sell signals of the WFME64 filter with the RMedV Indicator.
4/9/19 to 4/26/19

Table 1 Walk Forward Out-Of-Sample Performance Summary
EC-5 min bars RMedV Strategy with WFME64 Filter

EC 5 min bars 1/2/2008 - 4/26/19 OOS weekly performance using the below filter on each in-sample segment. The input values **N**, **vup**, **vdn** are the values found from applying the filter to the in-sample section.

In-sample Section Filter: $t15eqTrn|p \leq 2|ktau \leq 50-mWb|mLb$

Where:

osp = Weekly Out-of-sample gross profit in \$

ont = The number of trades in the out-of-sample week.

ollt = The largest losing trade in the out-of-sample section in \$.

odd = The drawdown in the out-of-sample section in \$.

Equity = Running Sum of weekly out-of-sample gross profits \$

osnp\$20 = Weekly Out-Of-Sample Net Profit in \$ = **osp**-**ont***20

NetEq = running sum of the weekly out-of-sample net profits (osnp\$20) in \$

N = N the lookback period

vup, the threshold amount that velocity has to be greater than to issue a buy signal

vdn, the threshold amount that velocity has to be less than to issue a sell signal

Note: Blank rows indicate that no out-of-sample trades were made that week

Appendix: The Normalization Multiplier

Repeated Median Velocity Normalization Multiplier

One of the inputs to the calculation of RMedV is N , the number of lookback bars. When we plot the RMedV we notice that the amplitude, and the maximum and minimum values of the RMedV vary quite significantly with different N inputs.

Below is a table, generated by the #iRMedVtMULTSTD indicator of the standard deviation(SD) of the 108333 calculated RMedV values for different N . We used 5 min bars of the CL from 3/8/2014 to 2/12/2016 to generate this table.

**@CL 5 min bars Date Range 1140803 to 1160212
Total Number of Bars=108333 Sqrt(n) Norm=0
Trading Times Constraint Start Time=800 EndTime=1430
RMedVx Multiplier to Scale RMedVx N Range to One Std**

**4 Std=0.0734077 1/std=13.6226
6 Std=0.056242 1/std=17.7803
8 Std=0.0470003 1/std=21.2765
10 Std=0.0414414 1/std=24.1304
12 Std=0.0375377 1/std=26.6399
14 Std=0.0346289 1/std=28.8776
16 Std=0.0322738 1/std=30.9849
18 Std=0.0302399 1/std=33.0689
20 Std=0.0285976 1/std=34.968
22 Std=0.0272164 1/std=36.7426
24 Std=0.0259991 1/std=38.4629
26 Std=0.0249334 1/std=40.1069
28 Std=0.0239323 1/std=41.7845
30 Std=0.0230171 1/std=43.446
1/Std Mult Average=30.8494**

As one can see the RMedV Standard Deviation for $N=4$ is over 3 times the SD for $N=30$. This makes it difficult to find a range for vup and vdn that satisfy all N . We would like to find a multiplier of the RMedV that normalizes all the RMedV standard deviations for any given N to the same SDs.

Fortunately, the SDs for the different N s for The RMedV are proportional to \sqrt{N} . So, if we multiply the RMedV by the \sqrt{N} , the RMedV for different N should have the same SDs and ranges. Below are the results for multiplying the RMedV by \sqrt{N} and computing it's standard deviation.

**@CL 5 min bars Date Range 1140803 to 1160212
Total Number of Bars=108333 Sqrt(n) Norm=1
Trading Times Constraint Start Time=800 EndTime=1430
RMedVx Multiplier to Scale RMedVx N Range to One Std**

4 Std=0.146815 1/std=6.81128
6 Std=0.137764 1/std=7.25878
8 Std=0.132937 1/std=7.52237
10 Std=0.131049 1/std=7.63072
12 Std=0.130034 1/std=7.69028
14 Std=0.12957 1/std=7.71786
16 Std=0.129095 1/std=7.74622
18 Std=0.128297 1/std=7.79441
20 Std=0.127892 1/std=7.81907
22 Std=0.127656 1/std=7.83354
24 Std=0.127369 1/std=7.8512
26 Std=0.127136 1/std=7.86561
28 Std=0.126638 1/std=7.89652
30 Std=0.12607 1/std=7.93212
1/Std Mult Average=7.66928

As we can see the SDs are now very close. If we multiply all RMedVs by $7.669 * \sqrt{N}$ then the SDs of the velocities for all will be normalized to 1. For this case 7.669 would be the multiplier *xmult*, in the strategy and indicator. This allows us to do an optimization search for ranges of vup and vdn from 0.2 to 3.4 standard deviations for all N.

Please note that different futures and different time bars give different multipliers.
