

Trading The E-Mini Using The End Point Fast Fourier Transform

Copyright © 2002 Dennis Meyers

In a previous article entitled “The Discrete Fourier Transform Illusion” we demonstrated the misuses of the mathematical technique called the Fourier Transform as applied to the S&P500 index. There we showed how fitting the Fourier Transform to the S&P500 index data series produced a perfect curve fit on past data giving the illusion that this technique would predict the major turning points of the S&P500 index. However, we demonstrated that when we examined the Fourier Transform on a day by day walk forward basis this seemingly wondrous predictive capability disappeared.

In the follow-up article entitled “The Endpoint Fast Fourier Transform System” we showed how to use the FFT in a technique called the End Point Fast Fourier Transform (EPFFT) to trade daily bars of the S&P 500 futures. Here it will be shown how to use EPFFT technique on a walk forward basis to trade 1 minute bars of the E-mini futures.

The FFT Illusion Review

Figure 1 presents the noise filtered FFT, as discussed in my previous article, on the SP from January 16, 1998 to January 22, 1999. The SP closing high was on July 20th, 1998. As can be seen from Figure 1 the FFT curve clearly leads the 7/20/1998 top and is pointing down on 7/20/98. This action gives the illusion that the FFT curve is a predictive indicator that leads the price series enabling one to escape the ensuing bear market drop. However, this FFT curve was generated on data from 1/16/98 to 1/22/99. What would our FFT curve look like if we generated our curve on July 20th, 1998? Figure 2 presents the noise filtered FFT on the SP from 7/15/97 to 7/20/98. As can be seen from the noise filtered FFT curve generated on 7/20/1998 the curve is pointing straight up giving no indication whatsoever of the coming large market drop. Why does this happen? When the FFT went to fit the data, it already knew where all the tops and bottoms were. The FFT mathematics minimize the error between the curve it generates and the real data points. This error minimization process forces the generated curve to smoothly fit the past data like a glove. As a matter of fact, it's almost impossible not to get an excellent fit.

The End Point FFT

In order to avoid the past data curve fit illusion, we will create an indicator that walks forward one bar at a time. This indicator will calculate the noise filtered FFT curve but only save the last point, or end point, of the curve on the day that it is calculated. We will then connect all the generated end points to produce a curve that matches what we would have seen if we performed the noise filtered FFT on the end point dates.

For example Figure 2 was calculated using data from 7/15/98 to 7/20/98. We would save the FFT curve point of 7/20/98 and slide our data window up one day from 7/16/98 to 7/21/98. We would calculate the noise filtered FFT of this new data window and save the FFT curve point of 7/21/98. We would keep sliding our data window forward one day at a time, calculate the noise filtered FFT and save the FFT curve end point. We would then connect all these saved endpoints to create a new curve which I have dubbed the End Point FFT or EPFFT for short. The EPFFT represents what we would observe in real time if we performed this procedure each day.

Figure 3 represents such a noise filtered EPFFT curve. For reasons that we will explain later in this article, the EPFFT curve is on a different scale than that of the SP prices. What's important

here is the shape of the EPFFT curve and where it's turning points occur. As we can observe from Figure 3, the EPFFT curve is quite different from the FFT curve in Figure 1. Instead of leading the SP closing price curve the EPFFT has anywhere from a zero day lag to a four day lag from the major tops and bottoms. The EPFFT had a zero day lag, peaking simultaneously with the SP futures at the futures top on 7/20/98.

EPFFT Construction Details

Unfortunately constructing the noise filtered FFT of a price data series is not quite as simple as just taking 512 closing prices, and directly plugging them into a FFT algorithm.

The mathematics of the Discrete Fourier Transform(DFT) assumes that the time-domain sample is periodic and that it has captured an integral number of periods. This means that the DFT assumes the end of the sampled series implicitly wraps around to the beginning to start all over again. Thus for 512 sampled data points the DFT assumes that these 512 sampled data points repeat every 512 samples. With real data series this is seldom the case and this creates what is called a wraparound effect in the frequency domain. The wraparound effect creates a lot of distortion on the ends of the price series when the noise filtered FFT is transformed back. Unfortunately the end point of the price series is the very point we wish to estimate. While we can do nothing about the wrap around violation, we can significantly lessen it's effects by what is called zero padding.

The DFT assumes the time domain sample is periodic and repeats. Suppose a price series starts at 400 and wiggles and wags for 512 data samples ending at the value of 600. The DFT assumes that the price series starts at zero, suddenly jumps to 400, goes to 600 and suddenly jumps down to zero again and then repeats. The DFT must create all kinds of different frequencies in the frequency domain to try and match this type of behavior. These false frequencies created to match the jumps and the high average price completely swamp the amplitudes of any real frequencies making them look like noise. Fortunately this effect can be almost eliminated by a simple technique called end point flattening.

The calculation of end point flattening coefficients is simple. If $x(1)$ represents the first price in the sampled data series, $x(n)$ represent the last point in the data series and $y(i)$ equal to the new endpoint flattened series then:

$$a = x(1) \quad b = (x(n) - x(1)) / (n - 1)$$

$$y(i) = x(i) - [a + b * (i - 1)] \quad \text{for } i = 1 \text{ to } n \quad (1)$$

We can see that when $i=1$ then $y(1)=0$ and when $i=n$ then $y(n)=0$. What we've done is subtract the beginning value of the time series to make the first value equal to zero and then rotate the rest of the time series such that the end point is now zero. This technique reduces the endpoint distortion but introduces a low frequency artifact into the Fourier Frequency spectrum.

EPFFT Curve Construction

For this article a sliding time-bar window of 512 1 minute bars of the E-Mini Sep/02 futures from 6/12/02 to 7/12/02 will be used. The first time window will be the 512 price bars from 6/12/02 to 6/13/02.

Step 1 Take the Log_e of the 512 prices to minimize the exponential trend movements of the E-mini. End flatten these 512 log prices using equation (1) above.

Step 2 Take the FFT of these 512 points to create 512 frequency domain complex numbers f_i .

Step 3 Use a Low Pass Threshold filter that zeros out the frequencies whose magnitudes are less than $\text{thres} * F_{\text{max}}$. Thres is the decimal percentage of F_{max} and F_{max} is the maximum frequency amplitude of the spectrum.

Step 4 Do an inverse FFT on the noise filtered spectrum and save the last 2 points. Although it's not obvious yet, we will need the noise filtered point one sample before the endpoint.

Add back the end point flattening of **Step 1** and taking the exponential value to reverse the log_e

Step 5 Save the filtered end point and the point before. Call the endpoint $ep(k)$ and the point before $ep1(k)$ where k is the denotes the order of the sliding window. That is, the first sliding window $k=1$, the second, $k=2$, etc. Slide the 512 bar data window forward one bar, and repeat steps 1 through 4.

When the data window is moved forward one bar at a time a new data sample is added to the end and the data sample at the beginning is subtracted. This adding and subtracting causes the end point flattening coefficients and the power in the frequency spectrum to jump around creating distortion and jitter in the calculation of the noise filtered end point. This random jumping of the FFT endpoints as the data window slides forward in time adds a random jump to FFT end point curve. Fortunately this jumping can be minimized by creating a new end point curve from the two saved noise filtered end points, $ep(k)$ and $ep1(k)$, above in step 5. Since turning points are of interest rather than magnitude then in **step 5** a new variable will be created called **sumEP** where

$$\text{sumEP}(k) = \text{sumEP}(k-1) + ep(k) - ep1(k)$$

This new curve **sumEP(k)** is the sum of all the changes in the individual $ep(k)$'s from their noise filtered FFT value one sample before. This change series minimizes the magnitude jump problem creating a fairly smooth EPFFT curve.

The EPFFT System Defined

Even though **sumEP** is a fairly smooth curve as seen in Figure 3, it still has a number of short term wiggles preventing us from simply going long when the curve turns up and going short when the curve turns down. To create a system, we will use a simple curve following technique.

Buy Rule:

- **IF sumEP** has moved up by more than the point amount of *pup* from the lowest low recorded in **sumEP** while short then buy the ES Sep/02 futures at the market..

Sell Rule:

- **IF sumEP** has moved down by more than the point amount *pdn* from the highest high recorded in **sumEP** while long then sell the ES Sep/02 futures at the market.

-

Intraday Bars Exit Rule:

Close the position 1 minute before the E-Mini close (no trades will be carried overnight).

Walk Forward Optimization

Walk forward optimization will be used here because of the changing nature of the intraday E-Mini futures market. Intraday price dynamics are constantly changing due to current economic surprises, events and trader sentiment. Also the time of year changes the nature of intraday markets, such as the seasons, holidays, vacation time, etc. As such, optimizations on intraday data performed 3 months ago may no longer be representative of today's intraday price dynamics.

The walk forward procedure will be applied as follows. A test period of 4 weeks of the ES Sep/02 1 minute bar data, June 12th, 2002 through July 12th, 2002, is chosen and system parameter values are found through optimization on this intraday data segment. The parameter values found are then applied to the out-of-sample 1 minute intraday bar data following the test segment which in this case is July 15th, 2002 to July 19th, 2002.

Why a 4 week intraday data test segment? There is no correct ratio of test data needed to produce good one week intraday out-of-sample results. By experimenting with different window lengths, the four to one ratio seemed to work well. In walk forward testing, enough data is needed to model most of the price dynamics that will be encountered in the out-of-sample segment, but not so much data that when the price dynamics start to change they are swamped by the weight of distant past data price dynamics that no longer apply. It is important to get good results over time in walk forward testing because if you can not get good results in the out-of-sample segments, then the price dynamics cannot be modeled with the system. This means that real time performance will not match the optimized curve fitted performance results and be random using the model. Traders observe this type of random performance (that is it looks great on paper but falls apart in real time) when trying systems based on optimization curve fitting or anecdotal "proof" (looking at 3 or 4 successful cases only) without any out-of-sample testing.

Finding The System Parameters Using Walk Forward Optimization

There are three system parameters to find *thres*, *pup*, and *pdn*. The best parameters will be defined as those values that give the best Net Profits with the maximum winning bars, minimum losing bars, minimum drawdown, minimum largest losing trades. In addition, the results should be stable, e.g. the profits, wins, and drawdowns should not change by much as the parameters move by a small amount away from their optimum values. Also in choosing the "best" parameters, only those parameters sets whose maximum consecutive losses were 4 or less were considered. Optimization is defined as the search for the parameter values that give the best results as defined above. It should be noted that in this stage of system development, the only thing indicated by the optimum values that are found in the test portion is that the data has been

curve fitted as best it can with this system. Without further testing on out-of-sample data there is no way to tell if the system will work in the future.

It is not well known, but almost any real time series or even a random time series defined over a fixed number of bars can be curve fitted rather easily. The performance results and the statistical measurements that validate this performance of the curve fit will look excellent giving the false illusion of future profitability. However, the truth is that these excellent performance and associated statistics on the test section in no way validate how the system will perform on data it has not been optimized on. Only out-of-sample testing, that is testing on data the parameters were not derived on, can determine if the parameters found in the test section have captured the price dynamics. For instance in the End Point FFT process the error minimization forces the generated curve to fit the past data like a glove. It's almost impossible not to get an excellent fit with excellent statistical results. Unfortunately, this excellent fit in no way implies that the system will perform equally well on out-of-sample data, it just tells us we have a very good curve fit.

Results

Figure 4 presents a table of the test window optimum parameters for the S&P Sep/99 5min data series.

Start Date	End Date	Thres	Pntup	Pntdn
06/12/02	07/12/02	0.13	2.75	1.25

Figure 4 Optimum Parameter Values For Test Data Segment

Figure 5 presents the performance summary of the test segment using the optimum parameters shown in Figure 4.

Figure 6 presents the performance summary of the out-of-sample data segment from 07/15/02 to 07/19/02. This performance represents what would have happened in *real time* if one used the parameters found in the test section. Slippage, and commissions are not included.

Figure 7 presents a trade by trade summary from 06/12/02 to 07/19/02.

Figures 8A through 8E present the out-of-sample 1 minute bar charts of the E-Mini Sep/02 futures with the EPFFT Curve and all the buy and sell signals from the trade by trade summary of Figure 7 indicated on the charts.

Discussion of System Performance

As can be observed from the test sample Performance summary in Figure 5 and the out-of-sample performance summary of Figure 6, the out-of-sample "All Trades" performance was similar to the test sample "All Trades" performance. This similar performance in average winning and losing trades and drawdowns indicate that 4 weeks of test data was enough to capture the intraday price dynamics of the E-Mini Sep/02 contract for one week into the future.

Observing the out-of-sample trade by trade summary of Figure 7, we can see that the system did much better on the short trades than it did on the long trades. This better short performance is due to the fact that the E-Mini future dropped almost 8% in the out-of-sample week. However,

to the systems credit, the one big upside rally on 7/15/02 that started at 2:38 EST at 877.5 was caught by the system at 2:49 at 884.5 and exited at the top at 920.25 on the close.

In observing the charts, we can see that the system did very well in catching every major intraday trend . Overall the **EPFFT** system did a good job in minimizing the losses due to the inevitable whipsaws that will occur in any trading system and maximizing the profits from the major intraday trend moves of the E-Mini futures.

In order to use this system in real time trading, at least ten to twenty more test and out-of-sample windows from the past would have to be examined to gain confidence that the results above were not due to pure chance.
